Peer-Reviewは検閲か?

After 1989 Schwinger took a keen interest in the research of low-energy nuclear fusion reactions (AKA cold fusion). He wrote eight theory papers about it. He resigned from the American Physical Society after their refusal to publish his papers. He felt that cold fusion research was being suppressed and academic freedom violated. He wrote: "The pressure for conformity is enormous. I have experienced it in editors' rejection of submitted papers, based on venomous criticism of anonymous referees. The replacement of impartial reviewing by censorship will be the death of science."

Nobel laureate Sir John Sulston, "ensuring the outputs of research are freely available to all is the best way to maximize its utility".

In principle, as Michael Mabe of the International Association of Scientific, Technical and Medical Publishers put it, this means that a single copy of a scientific paper might serve the whole planet. So calls for open access to the literature, free of institutional or financial constraints, can now readily be met, at least in technical terms.

Abstract: Efficient laser-diode pumped picosecond self-Q-switched all-ceramic composite Yb:YAG/Cr^{4+}:YAG microchip lasers with 0.72 MW peak power has been developed. Lasers with nearly diffraction-limited beam quality ($M^2 < 1.09$), oscillate at stable single- and multi- longitudinal-modes due to the combined etalon effects in the Yb:YAG and Cr^{4+}:YAG parts of its binary structure.

OCIS codes: (140.3380) Laser materials; (140.3480) Lasers, diode-pumped; (140.3540) Lasers, Q-switched; 140.5680 (Rare earth and transition metal solid-state lasers)

Maximum average output power of 610 mW was measured when the absorbed pump power was 3.28 W, corresponding to the optical-to-optical efficiency of 19%. There is no coating damage occurrence with further increase of the pump power, owing to the decrease of the intracavity energy fluence with high transmissio[n] of output coupler used. The transverse output beam profile is shown in inset (a) of Fig. 2. [It] transverse electromagnetic mode (TEM_{00}). Measu[red] focus are shown in inset (b) of Fig. 2. Near diffra[ction-limited] M_x^2 of 1.09 and M_y^2 of 1.07, respectively, was a[lso] near the output mirror was measured to be 100 μm [in] single-longitudinal-mode oscillation could be obtained by increasing the pump beam diameter incident on the laser ceramic at higher pump power.

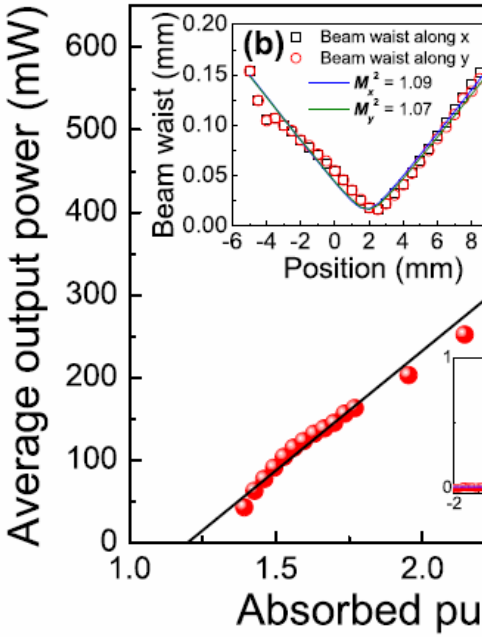

Fig. 2. Average output power as a function of [the] composite Yb:YAG/Cr^{4+}:YAG self-Q-switched m[icrochip] beam profile and transverse beam profile and (b) sh[ows]

There is thermal lens effect in such compa[ct] self-Q-switched lasers. The stability of plane-paral[lel] lens effect induced by heat generated inside the [laser] gain medium resulting from the absorbed

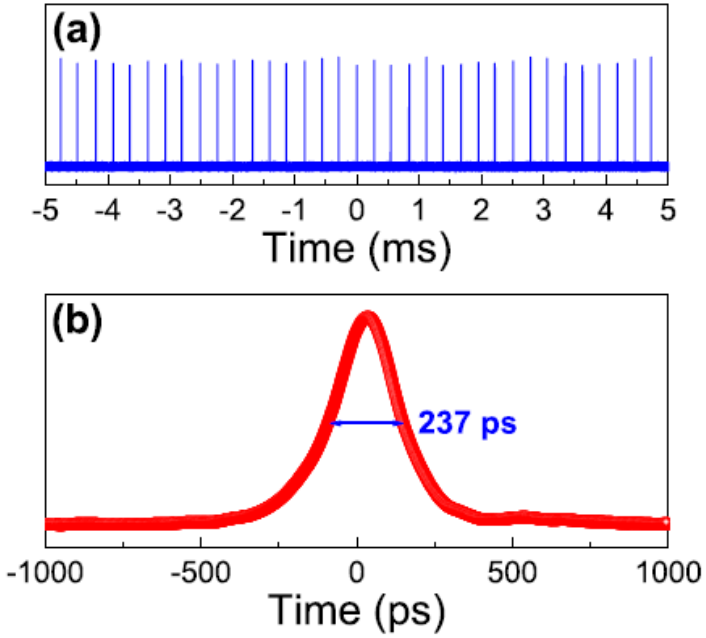

Fig. 4. (a) Oscilloscope trace of self-Q-switched all-ceramic composite Yb:YAG/Cr^{4+}:YAG microchip laser pulse trains; (b) self-Q-switched laser pulse with 237 ps pulse width (FWHM) and 172 μJ pulse energy, corresponding to peak power of over 0.72 MW.

Figure 4 shows the oscilloscope trace of the pulse trains and the output pulse with 237 ps pulse width (FWHM) and 172 μJ pulse energy. The output pulse amplitudes and repetition rate fluctuation are less than 6% [as shown in Fig. 4(a)], evidencing a very stable self-Q-switching laser operation. Over 0.72 MW laser pulses with the pulse width of 237 ps were obtained at a repetition rate of 3.5 kHz when the absorbed pump power is 3.28 W [as shown

Abstract. We present an experimental protocol that allows one to tune the packing fraction η of a random pile of ferromagnetic spheres from a value close to the lower limit of random loose packing $\eta_{RLP} \simeq 0.56$ to the upper limit of random close packing $\eta_{RCP} \simeq 0.64$. This broad range of packing fraction values is obtained under normal gravity in air, by adjusting a magnetic cohesion between the grains during the formation of the pile. Attractive and repulsive magnetic interactions are found to affect stongly the internal structure and the stability of sphere packing. After the formation of the pile, the induced cohesion is decreased continuously along a linear decreasing ramp. The controlled collapse of the pile is found to generate various and reproducible values of the random packing fraction η.

Contents

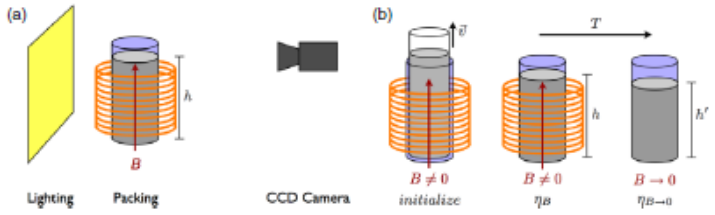

Figure 1. (a) Sketch of our experimental set-up. A high resolution camera (2048 × 2048 pixels) records the top of the packing placed in a glass tube. The pile is back-illuminated by a homogeneous lighting system. (b) Illustration of the pile creation and measurement protocol. Left: a smaller bottomless tube is inserted into the main glass cylinder. Then, a magnetic B field is applied through the packing. Afterward, this small tube is filled with spherical particles (in gray). The small tube is removed at constant speed v. Center: the position h of the upper grains allows the determination of the packing fraction η_B. Right: the magnetic field starts to decrease linearly to zero (reached after T seconds), the packing collapses partially and the new position h' of the upper grains gives an estimate of $\eta_{B\to 0}$.

grains during the pile preparation in order to control the packing fraction η of the pile. For this purpose, we consider ferromagnetic spherical beads which are submitted to an external magnetic field. After the formation of the pile, the magnetic field is decreased continuously along a linear ramp. This method to control experimentally the packing fraction opens new perspectives in the field of granular media and in the mathematical study of sphere packings.

(Received 20 November 2006 / Accepted 7 March 2007)

A new explanation regarding the toroidal spin-up of a field-reversed configuration (FRC) is provided. A physical picture showing that the poloidal flux can convert directly to kinetic angular momentum is described. Through the use of an ion orbit calculation in resistively decaying FRC plasma, toroidal rotation at both the separatrix and the field-null is found to occur.

Keywords: field-reversed configuration, toroidal spin-up, resistive flux decay, canonical angular momentum, inductive electric field

DOI: 10.1585/pfr.2.008

An $n = 2$ rotational instability of a field-reversed configuration (FRC) plasma has been observed experimentally and reported in several papers [1–3]. This instability originates from the centrifugal force which acts on a rotating FRC plasma. The origin of toroidal spin-up has not yet

direction. Generally, the separatrix radius decreases during the decay phase. If the guiding center r is also decreased, the toroidal velocity v_θ is further increased.

We can also explain FRC plasma rotation from the viewpoint of particle trajectories. In FRC plasma, a small-

Abstract

Recently a software package for the structure analysis of quasicrystals has been released, giving a better environment for determining quasicrystal structures. Therefore we can analyze their structures if we know data collection and indexing methods and a theory of structure analysis. For the use of the package, the structure analysis method and several techniques used in the package are shortly reviewed. How to treat key information in the input files of the programs is described in detail.

Keywords: software, quasicrystals, structure analysis

1. Introduction

Quasicrystals are special ordered structures which have non-crystallographic point groups including 5, 8, 10 or 12-fold axis, which never appear in conventional crystals. Their diffraction patterns, however, consist of the aggregates of Bragg reflections as in crystals. In the diffraction patterns, 5, 8, 10 or 12-fold rotation symmetry is found corresponding to the symmetry of quasicrystals. Most quasicrystals found so far are binary or ternary alloys [1]. It has been known already in 1986, that is, 2 years after the discovery of the first quasicrystals, that such a structure is obtained from a periodic structure in a higher-dimensional space by taking a three-dimensional (3*D*) intersection passing through an arbitrary point [2]. Therefore, the role of the structure analysis is to determine such a higher-dimensional periodic structure. Single (quasi-)crystals with enough size necessitated for the single crystal diffraction method had not been obtained for several years from the discovery but in 1987, the first such crystals were obtained [3] and after that single crystals for many quasicrystals have become obtainable [1]. Their extensive analyses have however been performed after 1997. (For detailed review before 1997, *see* [4].)

There are two types in quasicrystals. One is called polygonal (dihedral) quasicrystals, which have one 8, 10 or 12-fold axis and is periodic along this axis. They are called octagonal, decagonal and dodecagonal quasicrystals. These structure takes an ordered structure (quasiperiodic structure) in a plane normal to such a periodic axis. Another one called an icosahedral quasicrystal has no period along any directions.

Soon after the discovery, they had been considered to consist of some kinds of atomic clusters. Direct observations of quasicrystals by high-resolution electron microscopy played an important role for this [5]. If we employ this idea, it is easily conceivable that the structure description becomes easy by considering the clusters and atoms linking them. Noting this point, a higher-dimensional cluster model has been introduced [6]. In this model, we describe the clusters distributing in 3*D* space as a periodic structure in a higher-dimensional space. A software package based on this description has been written by the author and been released recently [7] (http://quasi.nims.go.jp/). In this paper, we describe shortly an analysis based on this program package.

The contents of the paper can be classified into three categories. The sections 1–7 are devoted to a short review of the structure analysis of quasicrystals. The following 9 sections describe on the software package and several calculation techniques employed in the package. Finally,

igure 2. ODs of the b-Ni phase in d-Al–Ni–Co quasicrystals. In), the OD is located at $(1, 1, 1, 1, 5z)/5$, while in (b), it is at $, 2, 2, 2, 5z)/5$ ($z = 1/4$).

e need to use the density and chemical composition of asicrystals as additional important information. The lattice nstant is not determined uniquely as mentioned above, t the point density of atoms (the number of atoms in a it volume) can be determined uniquely. We need to adjust e size and shape of the area (volume in icosahedral ones) the OD so as to give a correct density and chemical mposition. In addition, in the case where the approximant ystals are formed, we use the information from them. his is because we can frequently obtain the information clusters in quasicrystals. Furthermore, the density of the proximants is almost the same as that of quasicrystals. We sume for simplicity that the cluster structure is obtained om the structure analysis of the approximants. In addition, e suppose that the interpenetration of the clusters is not lowed.

In a higher-dimensional cluster model, we assume the rangement of clusters in quasicrystals. That is, we usually sume that the cluster center is located at vertices of some asiperiodic pattern. In the b-Ni phase, the OD shown in gure 2 was employed. (In this case, the inversion center is sumed, so that there are other two ODs which are related these two by the inversion. We abbreviate the description out such ODs. In the following, replace 'the OD 1 etc' ith 'the OD 1 and the other OD related to it by the version etc'.)

In this model, we assume that two kinds of clusters are cated at the vertices of a quasiperiodic pattern known as e Penrose pattern. This consists of two rhombi joined by lid lines seen in figure 3. As the two clusters, we consider those denoted by 1 and 2 in the same figure. After the determination of the ODs, we build a periodic structure in the *nD* space. After that we can calculate all the corresponding atom positions in the 3*D* space by taking a 3*D* intersection

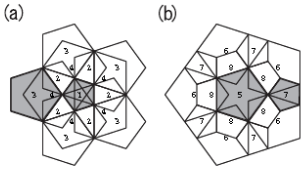

Figure 3. Structure model of the b-Ni phase in d-Al–Ni–Co quasicrystals projected along the 10-fold axis. A black circle represents the transition metal (Ni,Co) and gray, Al. The boat-shaped region located at the outermost part in figure 2 (a part of OD 3) and whole area of figure 2(b) are assumed to be occupied by Al. On the other hand, the transition metal positions are generated by the large pentagonal region except for the boats in figure 2(a).

of the periodic structure. It is known that the vertices of the Penrose pattern are generated from the two small gray pentagons labeled by 1 and 5 in figures 2(a) and (b) [15]. **qcstrc** is the program for calculating atom positions in 3*D* space for given ODs. The electron density in 3*D* space can be drawn by the program **qcmem**.

There exist two kinds of vertices around which there are 5 to 7 atoms and 10 atoms (denoted by 1 and 2 in figure 3). The former and latter comes from the ODs 1 and 5, respectively. We call clusters consisting of atoms around these cluster centers clusters 1 and 2. In figure 2, the large ODs consist of the pentagons similar to these but in some cases, they are partially overlapped. For example, the OD 6 is overlapped partially with the ODs 7 and 8. In figure 2, a part except for the central pentagons (ODs 1 and 5) generates peripheral atoms around the cluster center. In addition, a part shared by two ODs generates an atom position which are shared by two clusters. We can prove that an ODs, which generates an atom position far from the cluster center by a fixed distance in the external space, is obtained from the OD of the cluster center by shifting it by that distance along the external space. In the present case, such an OD is located at the peripheral of another large OD. As a result, depending on the kind of clusters, we may have a very complicated polygons with concave parts consisting of the aggregates of small ODs. This is a characteristic feature of quasicrystal structure models consisting of atom clusters. It is worth noting that even if the shape of the ODs is complicated, the principle leading to them is simple.

6. Closeness conditions

It is difficult to conceive that large holes are included in quasicrystals, since they are alloys. Therefore, we need to consider quasicrystals, which do not include such holes. It is also unrealistic that the structure shows an interatomic distance shorter than a value determined by the atomic radii. As a result, we need to consider a dense packing of atoms without including such shorter interatomic distances. Such a model imposes restrictions for the ODs.

n a model used. The input format of such yed in the program package was described on, the coordinate system for introducing positions in the external space was also icient use of similarity transformations in is of quasicrystals was discussed. Detailed of quasicrystals performed so far are a 6]. The author hopes that this package d and promote the structure analyses of
